Agricultural productivity,
Crude oil price,
Error correction,
Co-integration.

ABSTRACT
This study examined the effect of crude oil price on agricultural productivity in Nigeria between 1981 and 2010. Agricultural productivity (proxy as agricultural GDP) was specified as a function of factors such as exchange rate, crude oil price, capital stock, labour, land and fertilizer. Quantitative estimates, based on Augmented-Dickey Fuller (ADF) unit root test, Co-integration and Error Correction modelling, indicate that the exchange rate, capital, labour and trend are the major determinants of agricultural productivity in the long-run, while price of crude oil price is the most important determinant of agricultural productivity in the short–run. The results further shows that the error correction mechanism (ECM) indicated a feedback of about 112.5% of the previous year’s disequilibrium from long-run domestic agricultural production.

Introduction
The petroleum industry in Nigeria has brought unprecedented changes to the Nigerian economy, particularly in the past five decades when it replaced agriculture as the cornerstone of the Nigerian economy. The oil industry has risen to the commanding heights of the Nigerian economy, contributing the lion share to gross domestic product and accounting for the bulk of federal government revenue and foreign exchange earnings since early 1970. However, Nigeria’s considerable endowment in fossil fuel has not translated into an enviable economic performance; rather, the nation’s monocultural has assumed a precarious dimension in the past decades susceptible to the vagaries of the international oil markets.(Aigbedion and Iyayi, 2007)

The run up in crude oil prices was motivated initially by demand driven tightening of market balances; but has been further fuelled by a combination of supply concerns and financial factors. Market tightening is expected to persist because of a sluggish supply response. Beginning from the last quarter of 2008 demand pressures have eased as global output growth slowed, owing largely to the global economic and financial crisis. Oil prices are likely to remain volatile, arising from low stocks, limited spare capacity, supply disruptions, and uncertainty over exploiting new reserves and the development of non-oil sources. (Egwaikhide, 2012)

As an alternative to the large net seller of crude oil, many Nigerians today strongly believe that the nation should be free from any negative oil price shocks. However, the reality is a far cry from this expectation. Only few households seem to benefit from the oil windfall while others are subjected to further deprivation, higher food prices, higher transport costs and higher energy costs. On the other hand, there are groups of analysts who believe that the massive infrastructural development of the mid 1970s would have become the concern of all and no more the exclusive preserve of economists. (Egwaikhide, 2012).

The challenge of resuscitating agricultural production and development in Nigeria is an enormous one. This is because of the dramatic shift in the fortunes of the sector over the years: from the dominant sector of the economy (contributed 64.1 percent to GDP) and supplier of food, income, foreign exchange and employment in the 1960s to a net importer of food contributing less than 5 percent to total foreign exchange earnings in 2000. Many policy analysts attribute this to the sector’s neglect following the discovery of petroleum resources beginning from the early 1970s and the accompanying foreign exchange fortunes. Farming was not only abandoned, the structure of domestic demand for food and agricultural products was altered in favour of imports of grains, beverages and vegetable oils and fibres which Nigeria was once reputed as a leading world producer.(Oyekunle, 2013)

The task of resuscitating agricultural production for domestic use and exports is therefore very daunting. This would require finding solutions to the negative effects fluctuation in oil prices has cause agriculture in the country. Also, it would require stepping up production to meet and bridge the import gap provide for strategic food reserves and generate surplus for exports to earn income and sustain farming enterprise in general. It goes beyond resuscitation of traditional exports to conscious effort at developing and promoting new commodities for exports.

The overall objective of this study is to empirically assess the effect of crude oil price on agricultural productivity in Nigeria between 1981 and 2010 using a dynamic regression model. Specifically, co-integration and error correction model (ECM) is followed to give policy recommendations.

Conceptual framework and theoretical issues
In Nigeria, evidences exist regarding resource management and outcomes. Adeipibe (2004), Odutolu (2008), Van (2008), Akpan (2009). Adeipibe (2004)’s work focused on the impact of oil on Nigeria’s economic policy formulation from 1960 to 2000. Detailed descriptive analysis was explored. From the historical evaluation of economic policies it was evident that
prior to the discovery and extraction of oil in commercial quantity, agriculture was the mainstay of the Nigerian economy. However, with the advent of oil, unprecedented wealth accrued to the Nigerian government. This affected policy formulation. There were series of policy reversals which took its toll on the real sector of the economy; leading to its neglect. The author argues that the upstream sector of the oil industry in Nigeria.

The findings of Odularu (2008) who analysed the relationship between the crude oil sector and Nigeria’s economic performance were similar to Adebiaye (2004). Using Ordinary Least Square (OLS) regression method for the period 1970 to 2005, the findings revealed that crude oil consumption and exports had contributed positively to the improvement of the Nigerian economy. A striking issue emerging from the results is the finding that despite the positive relationship between domestic consumption and export of crude oil, the coefficient of crude oil export was insignificant. Plausible reasons advanced by the author, were, misappropriation of public funds (corruption), and poor administration. The author recommended the need for urgency in diversifying the export market especially the oil market, fight corruption and the encouragement of private sector participation in crude oil activities. A flaw observed in the analysis is the absence of some diagnostic tests on the specification to ascertain the appropriateness of the specification. Similarly, unit root tests were not conducted on the series to determine their stationarity or otherwise. In econometric analysis involving time series, this is crucial to avoid spurious regressions (Engle and Granger, 1987).

Using a VAR methodology, Akpan (2009) investigated oil price shocks and Nigeria’s macro economy for the period 1970 to 2007. The study pointed out the asymmetric effects of oil price shocks; for instance, positive as well as negative oil price shocks significantly increased inflation and also directly increased real national income through higher export earnings, though part of this gain was seen to be offset by losses from lower demand for exports generally due to the economic recession suffered by trading partners. The findings of the work further showed a strong positive relationship between positive oil price changes and real government expenditures. Unexpectedly, the result identified a marginal impact of oil price fluctuations on industrial output growth. Furthermore, the “Dutch Disease” syndrome was observed through significant real effective exchange rate appreciation. The result confirmed the neglect of the agricultural sector following the advent of oil observed by previous works (Adepibe, 2004, Odularu, 2008).

**Methodology**

**Analytical technique: Error correction and co-integration model:**

This study adopts the Johansen (1988) procedure in co-integration. The concept of co-integration (Hendry, 1986), (Hall, 1986) and (Mills, 1990), creates the link between integrated process and the concept of steady equilibrium. The first step in co-integration analysis is to test the order integration of the variables. Following Ajemomoh et al (2006), a series is said to be integrated if it accumulated some past effects, so that following any disturbance, the series will rarely return to any particular mean value, hence is non-stationary. Non-stationary of time series has always been regarded as a problem in econometric analysis. Philip (1986) shows that, in general, the statistical properties of regression analysis using non-time series are dubious notwithstanding promising diagnostic test statistics from such regression analysis. The order of integration is given by the number of times a series needs to be differenced so as to make it stationary. According to Charemza and Deadman (1992), a stochastic process is said to be stationary if the joint and conditional probability distributions of the processes are unchanged if displaced in time. If the series are co-integrated of the same order, a linear relationship between these variables can be estimated and examining the order of this linear relationship can test for co-integration. The grim fact is that economist look for the presence of stationary co-integrated relationships since only theses can be used to describe long-run stable equilibrium. The Granger representation theorem states that if set variables are co-integrated (1, 1); implying that the residual is co-integrated of 1(0), then there exists an error correction model describing the relationship.

**Model Specification**

Drawing from Hemphill (1974), Moran (1987), Udoh et al (1992), a stochastic process is said to be stationary if the joint statistical properties of regression analysis using non-time series econometric analysis. Philip (1986) shows that, in general, the number of times a series needs to be differenced so as to make it stationary. According to Charemza and Deadman (1992), a stochastic process is said to be stationary if the joint and conditional probability distributions of the processes are unchanged if displaced in time. If the series are co-integrated of the same order, a linear relationship between these variables can be estimated and examining the order of this linear relationship can test for co-integration. The grim fact is that economist look for the presence of stationary co-integrated relationships since only theses can be used to describe long-run stable equilibrium. The Granger representation theorem states that if set variables are co-integrated (1, 1); implying that the residual is co-integrated of 1(0), then there exists an error correction model describing the relationship.

**Model Specification**

Drawing from Hemphill (1974), Moran (1987), Udoh et al (1992), a stochastic process is said to be stationary if the joint statistical properties of regression analysis using non-time series econometric analysis. Philip (1986) shows that, in general, the number of times a series needs to be differenced so as to make it stationary. According to Charemza and Deadman (1992), a stochastic process is said to be stationary if the joint and conditional probability distributions of the processes are unchanged if displaced in time. If the series are co-integrated of the same order, a linear relationship between these variables can be estimated and examining the order of this linear relationship can test for co-integration. The grim fact is that economist look for the presence of stationary co-integrated relationships since only theses can be used to describe long-run stable equilibrium. The Granger representation theorem states that if set variables are co-integrated (1, 1); implying that the residual is co-integrated of 1(0), then there exists an error correction model describing the relationship.

**Error correction model**

First, the variables, in equation (1) were tested for unit root using the ADF technique while Johansen (1988) reduced-rank test for co-integration was used to test for co-integrations relationship between selected set of variables at crop level data. The error correction model (ECMs) estimated are shown in (2) below. ECM in (2) represents the short run behaviour of agricultural gross domestic product in (2) while equation (1) represents the long run static equations. The parameter λ, which is negative, in general measures the speed of adjustment towards the long run equilibrium relationship between the variables in (2). The optimum lag lengths to be included in equations (2) were determined based on Akaike Information Criterion (AIC).

**Static long run model for agricultural gross domestic product**

\[ LAGDP = \beta_1 + \beta_2 LEX + \beta_3 LP + \beta_4 LLb + \beta_5 LLd + \beta_6 LF + \gamma + \mu \]  

(1)

Error correction model (ECM) for the agricultural gross domestic product model is also given as equation (2)

\[ LAGDP = \beta_1 + \beta_2 LEX + \beta_3 LP + \beta_4 LLb + \beta_5 LLd + \beta_6 LF + \gamma + \mu \]  

(2)

where Δ represents first differencing, λ measures the extent of correction of errors by adjusting in independent variable, β measures the long-run elasticities while γ measures the short-run elasticities. General-to-specific modelling technique of Hendry and Ersson (1991) was followed in selecting the preferred ECM. This procedure first estimate the ECM with different lag lengths for the difference terms and, then, simplify the representation by eliminating the lags with insignificant parameters.

**Data and data source**

The data for this study is are time series data at macro level spanning from 1981 to 2010. The data were largely sourced from Food and Agricultural Organization (FAO) statistical data base for United Nations, Penn world data of the University of

**Results and discussion**

**Test for stationarity**

The results of the unit root tests are shown in Table 1. The null hypothesis of the presence of a unit root (non-stationarity) was tested against the alternative hypothesis of the absence of a unit root (stationarity). All the variables tested contain unit root processes, and all except two (land and fertilizer) became stationary after first difference. Hence, the variables are integrated of order 1 and 2; that is I (1) and I (2). This established the suitability of the variables with order I (1) for use in co-integration.

**Test for Co-integration**

Table 2 shows the Johansen test for evidence of co-integration relationship among selected variables. On application of the test, the results of the maximum-Eigen value statistics and trace statistics from the table 2 show that, there is at least 1 co-integration relation. This indicates that there exists a long-run relationship between all the explanatory variables and the explained variable. Since co-integration has been established, the regression results were analysed and diagnosed.

Short-run error correction results and diagnostics

The solved static long-run equation for agricultural productivity in Nigeria as well as its short – run equation is given in table 3 below. The $R^2$ value of 0.720 for the ECM in table 3 shows that the overall goodness of fit of the ECM is satisfactory. This means that only 72% of the variation in agricultural gross domestic product is explained by the explanatory variables, the remaining 28% is inherent in error term or white noise. However, a number of other diagnostic were also carried out in order to test the validity of the estimates and their suitability for policy discussion. The Autoregressive Conditional Heteroscedasticity (ARCH) test for testing heteroscedasticity in the error process in the model has an F-statistic of 0.556 which is statistically insignificant. This attests to the absence of heteroscedasticity in the model. The Jacque-Bera $\chi^2$ - statistic of 2.92 for the normality in the distribution in the error process shows that the error process is normally distributed. From the battery of diagnostic tests presented and discussed above, this study concludes that the model is well estimated and that the observed data fits the model specification adequately, thus the residuals are expected to be distributed as white noise and the coefficient valid for policy discussions.

It could be observed from the results in table 3 that the coefficient of error correction term (ECM) carries the expected negative sign and it is significant at 1%. The significance of the ECM supports co-integration and suggests the existence of long-run steady equilibrium between agricultural gross domestic product and other determining factors in the specified model. The coefficient of -1.125 indicates that the deviation of agricultural gross domestic product (AGDP) from the long-run equilibrium level is corrected by 112.5% in the current period.

The short-run coefficient of agricultural gross domestic product (LAGDP) in the immediate past period is 0.214. This result is positive and it could be due to increase in farmers’ output of crops along with improved producer price. This will probably have a positive impact on agricultural productivity in the current year.

The exchange rate ($LEX$) has a positive coefficient of 0.066 and 0.076 in the long and short-run respectively which are both significant at 5%. However, the short-run coefficient of exchange rate in the immediate past period is -0.06 and significant at 10%. This means that there has been an improvement in the devaluation of the currency in the current year. The elasticity values of exchange rate in both the short and long-run suggests that devaluation will decrease import of agricultural crops, thereby encouraging local production which will subsequently increase agricultural productivity.

In the short-run, crude oil price ($LP_o$) has a negative and significant coefficient of 0.04. However, in long-run, it has a negative but insignificant coefficient of 0.034. The elasticity value obtained for crude oil price in the short-run is in line with theoretical expectation since it is expected that as the world price of crude oil increase, the focus on agricultural productivity will further shift away. Also, the rapid rise in crude oil prices exerted an upwards pressure on food prices; as fertilizer prices nearly tripled and transport costs doubled over a two year period. At one time, agriculture contributes the larger percentage to the nation’s economy but the advent of crude oil exploration has contributed to the neglect of the agricultural sector. The results are in perfect agreement with the belief that, the advent of crude oil has affected the Nigerian agricultural sector negatively and significantly.

The coefficient of capital ($LK$) is significant only in the long-run with a value of 73.071 at 5% level. Though, it has a negative insignificant coefficient in the immediate past period; which means there has been an increased investment in the agricultural sector in the current year. It also has a positive but insignificant coefficient in the short run. This results means that a unit increase in capital investment in agriculture has the capacity to increase agricultural productivity, positively and significantly in the long run by 73.071 units.

In the long-run, labour ($LLb$) has a negative coefficient of -18.032 which is significant at 5%. However, in the short-run; it has a negative insignificant coefficient. This result means that a unit increase in labour will result in 18.032 workers decrease in agricultural productivity. This is probably because of the migration of the rural farming population to the urban areas as agriculture is predominantly practiced in the rural areas. Labour is usually measured in man-days especially in developing countries like Nigeria.

Time trend ($T$), which represents technology, was modelled into the series as represented by the time variable serving as proxy for the impact of technology change on productivity. It has a coefficient of 0.049 and it is significant at 5%. This result further justifies that capital and price factors are not sufficient to increase agricultural productivity in Nigeria; it takes a good combination of labour and structural factors, one of which is technology.

Source: Data Analysis, 2012. ***, ** and * indicates significant at 1%, 5%, and 10%

$ECM = LAGDP - 3988$

$-0.066LEX + 0.034LP_o - 73.071LK + 1803.2LLb$

**Conclusion and Policy recommendations**

This study reveals that crude oil price actually has a negative and significant effect on agricultural production in Nigeria. However, agricultural production in Nigeria can be increased by diversifying the economy; shifting focus away
from the export of crude oil only and more on the local production of agricultural produce and the export of its surplus. The agricultural population predominantly resident in the rural areas should be provided with basic social amenities and inputs at subsidized rate. The private sector along with the government should work together by investing in the agricultural sector especially in the areas of provision of modern production and processing technologies. These technologies are basically out of the reach of an average Nigerian farmer and if supplied, they will significantly increase agricultural production and contribute largely to the nation’s gross domestic product.
